Convolution model Step by Step v1

June 9, 2021

1 Convolutional Neural Networks: Step by Step

Welcome to Course 4's first assignment! In this assignment, you will implement convolutional (CONV) and pooling (POOL) layers in numpy, including both forward propagation and (optionally) backward propagation.

By the end of this notebook, you'll be able to:

- Explain the convolution operation
- Apply two different types of pooling operation
- Identify the components used in a convolutional neural network (padding, stride, filter, ...) and their purpose
- Build a convolutional neural network

Notation: - Superscript [l] denotes an object of the l^{th} layer. - Example: $a^{[4]}$ is the 4^{th} layer activation. $W^{[5]}$ and $b^{[5]}$ are the 5^{th} layer parameters.

- Superscript (i) denotes an object from the i^{th} example.
 - Example: $x^{(i)}$ is the i^{th} training example input.
- Subscript i denotes the i^{th} entry of a vector.
 - Example: $a_i^{[l]}$ denotes the i^{th} entry of the activations in layer l, assuming this is a fully connected (FC) layer.
- n_H, n_W and n_C denote respectively the height, width and number of channels of a given layer. If you want to reference a specific layer l, you can also write n_H^[l], n_W^[l], n_C^[l].
 n_{H_{prev}}, n_{W_{prev}} and n_{C_{prev}} denote respectively the height, width and number of channels of
- $n_{H_{prev}}$, $n_{W_{prev}}$ and $n_{C_{prev}}$ denote respectively the height, width and number of channels of the previous layer. If referencing a specific layer l, this could also be denoted $n_H^{[l-1]}$, $n_W^{[l-1]}$, $n_C^{[l-1]}$.

You should be familiar with numpy and/or have completed the previous courses of the specialization. Let's get started!

1 - Packages

Let's first import all the packages that you will need during this assignment. - numpy is the fundamental package for scientific computing with Python. - matplotlib is a library to plot graphs in Python. - np.random.seed(1) is used to keep all the random function calls consistent. This helps to grade your work.

```
[]: import numpy as np
import h5py
import matplotlib.pyplot as plt
from public_tests import *

//matplotlib inline
plt.rcParams['figure.figsize'] = (5.0, 4.0) # set default size of plots
plt.rcParams['image.interpolation'] = 'nearest'
plt.rcParams['image.cmap'] = 'gray'

//load_ext autoreload
//autoreload 2

np.random.seed(1)
```

2 - Outline of the Assignment

You will be implementing the building blocks of a convolutional neural network! Each function you will implement will have detailed instructions to walk you through the steps:

- Convolution functions, including:
 - Zero Padding
 - Convolve window

- Convolution forward
- Convolution backward (optional)
- Pooling functions, including:
 - Pooling forward
 - Create mask
 - Distribute value
 - Pooling backward (optional)

This notebook will ask you to implement these functions from scratch in numpy. In the next notebook, you will use the TensorFlow equivalents of these functions to build the following model:

Note: For every forward function, there is a corresponding backward equivalent. Hence, at every step of your forward module you will store some parameters in a cache. These parameters are used to compute gradients during backpropagation.

3 - Convolutional Neural Networks

Although programming frameworks make convolutions easy to use, they remain one of the hardest concepts to understand in Deep Learning. A convolution layer transforms an input volume into an output volume of different size, as shown below.

In this part, you will build every step of the convolution layer. You will first implement two helper functions: one for zero padding and the other for computing the convolution function itself.

```
\#\#\# 3.1 - Zero-Padding
```

Zero-padding adds zeros around the border of an image:

Figure 1: Zero-Padding Image (3 channels, RGB) with a padding of 2.

The main benefits of padding are:

- It allows you to use a CONV layer without necessarily shrinking the height and width of the volumes. This is important for building deeper networks, since otherwise the height/width would shrink as you go to deeper layers. An important special case is the "same" convolution, in which the height/width is exactly preserved after one layer.
- It helps us keep more of the information at the border of an image. Without padding, very few values at the next layer would be affected by pixels at the edges of an image.

Exercise 1 - zero_pad Implement the following function, which pads all the images of a batch of examples X with zeros. Use np.pad. Note if you want to pad the array "a" of shape (5, 5, 5, 5, 5) with pad = 1 for the 2nd dimension, pad = 3 for the 4th dimension and pad = 0 for the rest, you would do:

```
a = np.pad(a, ((0,0), (1,1), (0,0), (3,3), (0,0)), mode='constant', constant values = (0,0))
```

```
[]: # GRADED FUNCTION: zero_pad

def zero_pad(X, pad):
    """

    Pad with zeros all images of the dataset X. The padding is applied to the
    →height and width of an image,
    as illustrated in Figure 1.
```

```
Argument:

X -- python numpy array of shape (m, n_H, n_W, n_C) representing a batch of → m images

pad -- integer, amount of padding around each image on vertical and → horizontal dimensions

Returns:

X_pad -- padded image of shape (m, n_H + 2 * pad, n_W + 2 * pad, n_C)

"""

#( 1 line)

# X_pad = None

# YOUR CODE STARTS HERE

# YOUR CODE ENDS HERE

return X_pad
```

```
[]: np.random.seed(1)
     x = np.random.randn(4, 3, 3, 2)
     x_pad = zero_pad(x, 3)
     print ("x.shape = \n", x.shape)
     print ("x pad.shape = \n", x pad.shape)
     print ("x[1,1] = n", x[1, 1])
     print (x_{pad}[1,1] = n, x_{pad}[1,1])
     assert type(x_pad) == np.ndarray, "Output must be a np array"
     assert x_pad.shape == (4, 9, 9, 2), f"Wrong shape: \{x_pad.shape\}!= (4, 9, 9, 1)
     ⇔2)"
     print(x_pad[0, 0:2,:, 0])
     assert np.allclose(x_pad[0, 0:2,:, 0], [[0, 0, 0, 0, 0, 0, 0, 0, 0], [0, 0, 0, 0]
     \rightarrow 0, 0, 0, 0, 0]], 1e-15), "Rows are not padded with zeros"
     assert np.allclose(x_pad[0, :, 7:9, 1].transpose(), [[0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0]
     →0], [0, 0, 0, 0, 0, 0, 0, 0]], 1e-15), "Columns are not padded with zeros"
     assert np.allclose(x_pad[:, 3:6, 3:6, :], x, 1e-15), "Internal values are_
     ⊸different"
     fig, axarr = plt.subplots(1, 2)
     axarr[0].set_title('x')
     axarr[0].imshow(x[0, :, :, 0])
     axarr[1].set_title('x_pad')
     axarr[1].imshow(x_pad[0, :, :, 0])
     zero_pad_test(zero_pad)
```

3.2 - Single Step of Convolution

In this part, implement a single step of convolution, in which you apply the filter to a single position of the input. This will be used to build a convolutional unit, which:

- Takes an input volume
- Applies a filter at every position of the input
- Outputs another volume (usually of different size)

Figure 2: Convolution operation with a filter of 3x3 and a stride of 1 (stride = amount you move the window each time you slide)

In a computer vision application, each value in the matrix on the left corresponds to a single pixel value. You convolve a 3x3 filter with the image by multiplying its values element-wise with the original matrix, then summing them up and adding a bias. In this first step of the exercise, you will implement a single step of convolution, corresponding to applying a filter to just one of the positions to get a single real-valued output.

Later in this notebook, you'll apply this function to multiple positions of the input to implement the full convolutional operation.

```
### Exercise 2 - conv_single_step Implement conv_single_step().
```

Hint.

Note: The variable b will be passed in as a numpy array. If you add a scalar (a float or integer) to a numpy array, the result is a numpy array. In the special case of a numpy array containing a single value, you can cast it as a float to convert it to a scalar.

```
[]: # GRADED FUNCTION: conv single step
     def conv single step(a slice prev, W, b):
         Apply one filter defined by parameters W on a single slice (a slice prev),
      ⇒of the output activation
         of the previous layer.
         Arguments:
         a_slice_prev -- slice of input data of shape (f, f, n_C_prev)
         W -- Weight parameters contained in a window - matrix of shape (f, f, \downarrow)
      \hookrightarrow n C prev)
         b -- Bias parameters contained in a window - matrix of shape (1, 1, 1)
         Returns:
         Z -- a scalar value, the result of convolving the sliding window (W, b) on
      \rightarrowa slice x of the input data
         #( 3 lines of code)
         # Element-wise product between a slice prev and W. Do not add the bias yet.
         \# s = None
         # Sum over all entries of the volume s.
```

```
# Add bias b to Z. Cast b to a float() so that Z results in a scalar value.
# Z = None
# YOUR CODE STARTS HERE

# YOUR CODE ENDS HERE
return Z
```

```
[]: np.random.seed(1)
a_slice_prev = np.random.randn(4, 4, 3)
W = np.random.randn(4, 4, 3)
b = np.random.randn(1, 1, 1)

Z = conv_single_step(a_slice_prev, W, b)
print("Z =", Z)
conv_single_step_test(conv_single_step)

assert (type(Z) == np.float64 or type(Z) == np.float32), "You must cast the
output to float"
assert np.isclose(Z, -6.999089450680221), "Wrong value"
```

3.3 - Convolutional Neural Networks - Forward Pass

In the forward pass, you will take many filters and convolve them on the input. Each 'convolution' gives you a 2D matrix output. You will then stack these outputs to get a 3D volume:

Exercise 3 - conv_forward Implement the function below to convolve the filters W on an input activation A_prev.

This function takes the following inputs: * A_prev, the activations output by the previous layer (for a batch of m inputs); * Weights are denoted by W. The filter window size is f by f. * The bias vector is b, where each filter has its own (single) bias.

You also have access to the hyperparameters dictionary, which contains the stride and the padding.

Hint: 1. To select a 2x2 slice at the upper left corner of a matrix "a_prev" (shape (5,5,3)), you would do:

```
a_slice_prev = a_prev[0:2,0:2,:]
```

Notice how this gives a 3D slice that has height 2, width 2, and depth 3. Depth is the number of channels.

This will be useful when you will define a_slice_prev below, using the start/end indexes you will define.

2. To define a_slice you will need to first define its corners vert_start, vert_end, horiz_start and horiz_end. This figure may be helpful for you to find out how each of the corners can be defined using h, w, f and s in the code below.

Figure 3: Definition of a slice using vertical and horizontal start/end (with a 2x2 filter) This figure shows only a single channel.

Reminder:

The formulas relating the output shape of the convolution to the input shape are:

$$n_{H} = \left\lfloor \frac{n_{H_{prev}} - f + 2 \times pad}{stride} \right\rfloor + 1$$

$$n_{W} = \left\lfloor \frac{n_{W_{prev}} - f + 2 \times pad}{stride} \right\rfloor + 1$$

 n_C = number of filters used in the convolution

For this exercise, don't worry about vectorization! Just implement everything with for-loops.

Additional Hints (if you're stuck):

- Use array slicing (e.g.varname[0:1,:,3:5]) for the following variables:
 a_prev_pad ,W, b
 - Copy the starter code of the function and run it outside of the defined function, in separate cells.
 - Check that the subset of each array is the size and dimension that you're expecting.
- To decide how to get the vert_start, vert_end, horiz_start, horiz_end, remember that these are indices of the previous layer.
 - Draw an example of a previous padded layer (8 x 8, for instance), and the current (output layer) (2 x 2, for instance).
 - The output layer's indices are denoted by h and w.
- Make sure that a_slice_prev has a height, width and depth.
- Remember that a_prev_pad is a subset of A_prev_pad.
 - Think about which one should be used within the for loops.

```
def conv_forward(A_prev, W, b, hparameters):
    """
    Implements the forward propagation for a convolution function

Arguments:
    A_prev -- output activations of the previous layer,
        numpy array of shape (m, n_H_prev, n_W_prev, n_C_prev)
    W -- Weights, numpy array of shape (f, f, n_C_prev, n_C)
    b -- Biases, numpy array of shape (1, 1, 1, n_C)
    hparameters -- python dictionary containing "stride" and "pad"

Returns:
    Z -- conv output, numpy array of shape (m, n_H, n_W, n_C)
    cache -- cache of values needed for the conv_backward() function
```

```
n n n
   # Retrieve dimensions from A prev's shape (1 line)
   # (m, n_H_prev, n_W_prev, n_C_prev) = None
   # Retrieve dimensions from W's shape (1 line)
   # (f, f, n_C_prev, n_C) = None
   # Retrieve information from "hparameters" (2 lines)
   # stride = None
   # pad = None
   \# Compute the dimensions of the CONV output volume using the formula given
\rightarrowabove.
   # Hint: use int() to apply the 'floor' operation. (2 lines)
   \# n_H = None
   # n W = None
   # Initialize the output volume Z with zeros. (1 line)
   \# Z = None
   # Create A_prev_pad by padding A_prev
   # A_prev_pad = None
   # for i in range(None):
                                         # loop over the batch of training_
\rightarrow examples
       # a prev pad = None
                                          # Select ith training example's
\rightarrow padded activation
       # for h in range(None):
                                          # loop over vertical axis of the
→output volume
            # Find the vertical start and end of the current "slice" (2 lines)
           # vert_start = None
           # vert end = None
           # for w in range(None): # loop over horizontal axis of the
\rightarrow output volume
               # Find the horizontal start and end of the current "slice" (24
\rightarrow lines)
                # horiz start = None
                # horiz_end = None
                # for c in range(None): # loop over channels (= \#filters) of
\hookrightarrow the output volume
                    # Use the corners to define the (3D) slice of a_prev_pad_
\hookrightarrow (See Hint above the cell). (1 line)
```

```
# a_slice_prev = None

# Convolve the (3D) slice with the correct filter W and \( \)

$\infty$ bias b, to get back one output neuron. (3 line)

# weights = None

# biases = None

# Z[i, h, w, c] = None

# YOUR CODE STARTS HERE

# YOUR CODE ENDS HERE

# Save information in "cache" for the backprop cache = (A_prev, W, b, hparameters)

return Z, cache
```

Finally, a CONV layer should also contain an activation, in which case you would add the following line of code:

```
# Convolve the window to get back one output neuron
Z[i, h, w, c] = ...
# Apply activation
A[i, h, w, c] = activation(Z[i, h, w, c])
You don't need to do it here, however.
```

4 - Pooling Layer

The pooling (POOL) layer reduces the height and width of the input. It helps reduce computation, as well as helps make feature detectors more invariant to its position in the input. The two types of pooling layers are:

• Max-pooling layer: slides an (f, f) window over the input and stores the max value of the window in the output.

• Average-pooling layer: slides an (f, f) window over the input and stores the average value of the window in the output.

These pooling layers have no parameters for backpropagation to train. However, they have hyper-parameters such as the window size f. This specifies the height and width of the $f \times f$ window you would compute a max or average over.

4.1 - Forward Pooling Now, you are going to implement MAX-POOL and AVG-POOL, in the same function.

Exercise 4 - pool_forward

Implement the forward pass of the pooling layer. Follow the hints in the comments below.

Reminder: As there's no padding, the formulas binding the output shape of the pooling to the input shape is:

$$n_H = \left\lfloor \frac{n_{H_{prev}} - f}{stride} \right\rfloor + 1$$

$$n_W = \left\lfloor \frac{n_{W_{prev}} - f}{stride} \right\rfloor + 1$$

$$n_C = n_{C_{prev}}$$

```
[ ]: # GRADED FUNCTION: pool forward
     def pool_forward(A_prev, hparameters, mode = "max"):
         Implements the forward pass of the pooling layer
         Arguments:
         A_prev -- Input data, numpy array of shape (m, n_H_prev, n_W_prev, n_C_prev)
         hparameters -- python dictionary containing "f" and "stride"
         mode -- the pooling mode you would like to use, defined as a string ("max",
      →or "average")
         Returns:
         A -- output of the pool layer, a numpy array of shape (m, n_H, n_W, n_C)
         cache -- cache used in the backward pass of the pooling layer, contains the __
      \hookrightarrow input and hparameters
         11 11 11
         # Retrieve dimensions from the input shape
         (m, n_H_prev, n_W_prev, n_C_prev) = A_prev.shape
         # Retrieve hyperparameters from "hparameters"

```

What you should remember:

- A convolution extracts features from an input image by taking the dot product between the input data and a 2D array of weights (the filter).
- The 2D output of the convolution is called the feature map
- A convolution layer is where the filter slides over the image and computes the dot product
 This transforms the input volume into an output volume of different size
- Zero padding helps keep more information at the image borders, and is helpful for building deeper networks, because you can build a CONV layer without shrinking the height and width of the volumes
- Pooling layers gradually reduce the height and width of the input by sliding a 2D window over each specified region, then summarizing the features in that region

Congratulations! You have now implemented the forward passes of all the layers of a convolutional network. Great work!

The remainder of this notebook is optional, and will not be graded. If you carry on, just remember to hit the Submit button to submit your work for grading first.

```
## 5 - Backpropagation in Convolutional Neural Networks (OPTIONAL / UNGRADED)
```

In modern deep learning frameworks, you only have to implement the forward pass, and the framework takes care of the backward pass, so most deep learning engineers don't need to bother with the details of the backward pass. The backward pass for convolutional networks is complicated.

If you wish, you can work through this optional portion of the notebook to get a sense of what backprop in a convolutional network looks like.

When in an earlier course you implemented a simple (fully connected) neural network, you used backpropagation to compute the derivatives with respect to the cost to update the parameters. Similarly, in convolutional neural networks you can calculate the derivatives with respect to the cost in order to update the parameters. The backprop equations are not trivial and were not derived in lecture, but are briefly presented below.

5.1 - Convolutional Layer Backward Pass

Let's start by implementing the backward pass for a CONV layer.

5.1.1 - Computing dA: This is the formula for computing dA with respect to the cost for a certain filter W_c and a given training example:

$$dA += \sum_{h=0}^{n_H} \sum_{w=0}^{n_W} W_c \times dZ_{hw}$$
 (1)

Where W_c is a filter and dZ_{hw} is a scalar corresponding to the gradient of the cost with respect to the output of the conv layer Z at the hth row and wth column (corresponding to the dot product taken at the ith stride left and jth stride down). Note that at each time, you multiply the the same filter W_c by a different dZ when updating dA. We do so mainly because when computing the forward propagation, each filter is dotted and summed by a different a_slice. Therefore when computing the backprop for dA, you are just adding the gradients of all the a_slices.

In code, inside the appropriate for-loops, this formula translates into:

da_prev_pad[vert_start:vert_end, horiz_start:horiz_end, :] += W[:,:,:,c] * dZ[i, h, w, c]

5.1.2 - Computing dW: This is the formula for computing dW_c (dW_c is the derivative of one filter) with respect to the loss:

$$dW_c += \sum_{h=0}^{n_H} \sum_{w=0}^{n_W} a_{slice} \times dZ_{hw}$$
 (2)

Where a_{slice} corresponds to the slice which was used to generate the activation Z_{ij} . Hence, this ends up giving us the gradient for W with respect to that slice. Since it is the same W, we will just add up all such gradients to get dW.

In code, inside the appropriate for-loops, this formula translates into:

$$dW[:,:,:,c] \setminus a_slice * dZ[i, h, w, c]$$

5.1.3 - Computing db:

This is the formula for computing db with respect to the cost for a certain filter W_c :

$$db = \sum_{h} \sum_{w} dZ_{hw} \tag{3}$$

As you have previously seen in basic neural networks, db is computed by summing dZ. In this case, you are just summing over all the gradients of the conv output (Z) with respect to the cost.

In code, inside the appropriate for-loops, this formula translates into:

```
db[:,:,:,c] += dZ[i, h, w, c]
### Exercise 5 - conv_backward
```

Implement the conv_backward function below. You should sum over all the training examples, filters, heights, and widths. You should then compute the derivatives using formulas 1, 2 and 3 above.

```
[]: def conv backward(dZ, cache):
         Implement the backward propagation for a convolution function
         Arguments:
         dZ -- gradient of the cost with respect to the output of the conv layer \Box
      \rightarrow (Z), numpy array of shape (m, n_H, n_W, n_C)
         cache -- cache of values needed for the conv_backward(), output of \Box
      \rightarrow conv\_forward()
         Returns:
         dA prev -- gradient of the cost with respect to the input of the conv layer
      \hookrightarrow (A_prev),
                     numpy array of shape (m, n_H_prev, n_W_prev, n_C_prev)

## 5.2 Pooling Layer - Backward Pass
```

Next, let's implement the backward pass for the pooling layer, starting with the MAX-POOL layer. Even though a pooling layer has no parameters for backprop to update, you still need to backpropagate the gradient through the pooling layer in order to compute gradients for layers that came before the pooling layer.

```
\#\#\# 5.2.1 Max Pooling - Backward Pass
```

Before jumping into the backpropagation of the pooling layer, you are going to build a helper function called create_mask_from_window() which does the following:

$$X = \begin{bmatrix} 1 & 3 \\ 4 & 2 \end{bmatrix} \quad \to \quad M = \begin{bmatrix} 0 & 0 \\ 1 & 0 \end{bmatrix} \tag{4}$$

As you can see, this function creates a "mask" matrix which keeps track of where the maximum of the matrix is. True (1) indicates the position of the maximum in X, the other entries are False (0). You'll see later that the backward pass for average pooling is similar to this, but uses a different mask.

```
### Exercise 6 - create_mask_from_window
```

Implement $create_mask_from_window()$. This function will be helpful for pooling backward. Hints: - np.max() may be helpful. It computes the maximum of an array. - If you have a matrix X and a scalar x: A = (X == x) will return a matrix A of the same size as X such that:

```
A[i,j] = True if X[i,j] = x

A[i,j] = False if X[i,j] != x
```

• Here, you don't need to consider cases where there are several maxima in a matrix.

```
[]: def create_mask_from_window(x):
    """
    Creates a mask from an input matrix x, to identify the max entry of x.

    Arguments:
    x -- Array of shape (f, f)

    Returns:
    mask -- Array of the same shape as window, contains a True at the position
    →corresponding to the max entry of x.
    """
    # (1 line)
    # mask = None
    # YOUR CODE STARTS HERE

    **# YOUR CODE ENDS HERE**
    return mask
```

```
[]: np.random.seed(1)
x = np.random.randn(2, 3)
```

```
\mathbf{x} =
```

```
 [[\ 1.62434536\ -0.61175641\ -0.52817175]\ [-1.07296862\ 0.86540763\ -2.3015387\ ]]   mask =
```

[[True False False] [False False False]]

Why keep track of the position of the max? It's because this is the input value that ultimately influenced the output, and therefore the cost. Backprop is computing gradients with respect to the cost, so anything that influences the ultimate cost should have a non-zero gradient. So, backprop will "propagate" the gradient back to this particular input value that had influenced the cost.

```
\#\#\# 5.2.2 - Average Pooling - Backward Pass
```

In max pooling, for each input window, all the "influence" on the output came from a single input value—the max. In average pooling, every element of the input window has equal influence on the output. So to implement backprop, you will now implement a helper function that reflects this.

For example if we did average pooling in the forward pass using a 2x2 filter, then the mask you'll use for the backward pass will look like:

$$dZ = 1 \quad \rightarrow \quad dZ = \begin{bmatrix} 1/4 & 1/4 \\ 1/4 & 1/4 \end{bmatrix} \tag{5}$$

This implies that each position in the dZ matrix contributes equally to output because in the forward pass, we took an average.

```
### Exercise 7 - distribute value
```

Implement the function below to equally distribute a value dz through a matrix of dimension shape.

Hint

```
[]: def distribute_value(dz, shape):
         Distributes the input value in the matrix of dimension shape
         Arguments:
         dz -- input scalar
         shape -- the shape (n_H, n_W) of the output matrix for which we want to_{\sqcup}
      \hookrightarrow distribute the value of dz
         Returns:
         a -- Array of size (n_H, n_W) for which we distributed the value of dz
         # Retrieve dimensions from shape (1 line)
         \# (n_H, n_W) = None
         # Compute the value to distribute on the matrix (1 line)
         # average = None
         # Create a matrix where every entry is the "average" value (1 line)
         \# a = None
         # YOUR CODE STARTS HERE
         # YOUR CODE ENDS HERE
         return a
     print('distributed value =', a)
```

```
a = distribute_value(2, (2, 2))
print('distributed value =', a)

assert type(a) == np.ndarray, "Output must be a np.ndarray"
assert a.shape == (2, 2), f"Wrong shape {a.shape} != (2, 2)"
assert np.sum(a) == 2, "Values must sum to 2"

a = distribute_value(100, (10, 10))
assert type(a) == np.ndarray, "Output must be a np.ndarray"
assert a.shape == (10, 10), f"Wrong shape {a.shape} != (10, 10)"
assert np.sum(a) == 100, "Values must sum to 100"

print("\033[92m All tests passed.")
```

Expected Output:

```
distributed_value =  [[ 0.5 \ 0.5] < br > [ 0.5 \ 0.5] ]
```

5.2.3 Putting it Together: Pooling Backward

You now have everything you need to compute backward propagation on a pooling layer.

```
### Exercise 8 - pool_backward
```

Implement the pool_backward function in both modes ("max" and "average"). You will once again use 4 for-loops (iterating over training examples, height, width, and channels). You should use an if/elif statement to see if the mode is equal to 'max' or 'average'. If it is equal to 'average' you should use the distribute_value() function you implemented above to create a matrix of the same shape as a_slice. Otherwise, the mode is equal to 'max', and you will create a mask with create_mask_from_window() and multiply it by the corresponding value of dA.

```
[]: def pool_backward(dA, cache, mode = "max"):
         11 11 11
         Implements the backward pass of the pooling layer
         Arguments:
         dA -- gradient of cost with respect to the output of the pooling layer,
      \hookrightarrow same shape as A
         cache -- cache output from the forward pass of the pooling layer, contains \sqcup
      → the layer's input and hparameters
         mode -- the pooling mode you would like to use, defined as a string ("max"_{\sqcup}
      →or "average")
         Returns:
         dA_prev -- gradient of cost with respect to the input of the pooling layer, __
      \hookrightarrow same shape as A_prev
         # Retrieve information from cache (1 line)
